Histidine and Aromatic Permeases of 
Salmonella typhimurium

GIOVANNA F. AMES AND JOHN R. ROTH

Departments of Biochemistry and Molecular Biology, University of California, Berkeley, California 94720

Received for publication 9 September 1968

Mutants defective either in the histidine permease (hisP) or in the aromatic permease (aroP) were isolated in Salmonella typhimurium and were characterized. The hisP locus had a 49% linkage to purF by phage transduction. The aroP locus was close to proA. Merozygotes diploid for the hisP gene were constructed by episomal transfer, and hisP+ was dominant over hisP. The properties of merozygotes are described and discussed. A method for the selection of revertants of hisP mutants was devised. By this method, one of the hisP mutants was characterized as an amber mutant. The specificity of the aromatic permease was investigated by using as substrates analogues of the aromatic amino acids and of histidine.

Some properties of the active transport of histidine and of the aromatic amino acids in Salmonella typhimurium have been previously presented (1, 12). Preliminary results demonstrated that amino acids are incorporated into lipidic compounds, and the possible role of these compounds in transport has been discussed (2). This paper describes further studies on the genetics and properties of active transport mutants.

Two permeases are capable of transporting histidine in S. typhimurium: a specific histidine permease and an aromatic permease (1, 12). The histidine permease (which is highly specific for histidine and has a $K_m$ of $8 \times 10^{-4}$) also transports the histidine analogue, $d(+)-\alpha$-hydrazinimidazolepropionic acid (HIPA), which is a powerful inhibitor of growth of S. typhimurium (13). A mutant resistant to inhibition by HIPA was selected and demonstrated to have a defective histidine-specific permease (12). Mutants of this type are designated hisP.

In this paper, we describe additional characteristics of the hisP mutants, including the map position of the hisP locus, a method for selecting revertants of hisP mutations, the dominance of hisP+ over hisP, the phenotype of episome-containing strains which carry either two copies of the wild-type hisP+ gene or only an episomal hisP+ gene, and the isolation of amber hisP mutations.

The general aromatic permease (1) transports phenylalanine, tyrosine, tryptophan, histidine, and numerous analogues of each of these amino acids. The affinity for the aromatic amino acids is very high (the $K_m$ values are all about $10^{-3}$), whereas the affinity for histidine is very much lower ($K_m$, $10^{-4}$) than that of the histidine permease. The aromatic permease also transports a glutamine analogue, azaserine, which inhibits the growth of S. typhimurium. Mutants with a defective aromatic permease have been isolated as strains resistant to inhibition by azaserine and have been designated aroP (1). (Those azaserine-resistant mutants (aza) having an altered aromatic permease are now designated aroP. Mutant aza-3 (1) is now designated aroP504.)

Mapping of the aroP locus and additional properties of the general aromatic permease are also reported.

MATERIALS AND METHODS

Strains. All strains used were derived from S. typhimurium strain LT-2. Strain SR305 (HfrA, gal-30, hisD23) was obtained from the collection of M. Demerec. Multiply marked strain SL751 (ile-405 proA446 purC7 str-r rha-461 fla-56 iM-10 fim⁺) was obtained from the collection of B. A. D. Stocker. Histidine permease mutant hisP1650 (12) and aromatic permease mutant aroP504 (1) have been previously described. All other strains were obtained from P. E. Hartman and B. N. Ames.

Double-mutants TA235 (hisHB22 hisP1657) and TA242 (hisHB22 hisP1661) were constructed by selecting for HIPA-resistant mutants of strain hisHB22 on medium containing $3 \times 10^{-4}$ M HIPA and $3 \times 10^{-4}$ M L-histidinol (histidinol is not transported by the histidine permease). All other strains containing either hisP or aroP mutations were constructed by selection for HIPA or azaserine resistance, respectively, with the appropriate parental strains. TA 236 (ile-405 proA446 purC7 str-r rha-461 fla-56 iM-10 fim⁺ hisP1655) and TA237 (ile-405 proA446
perC7 str-r rha-461 fla-56 iM-10 fim- arD505) were derived from SL751.

Strain TR11 (aroD5 cysC1112/F'32 arD+ dsd) was constructed by infecting SB259 (aroD5 cysC1112) with the F'32 episome. The Escherichia coli episome F'32 was isolated and kindly donated by E. McFall (8). Strains TR134 (purF145 hisP1653/F'32 dsd) and TR135 (purF145/F'32 dsd) were constructed by infecting strains purF145 hisP1653 and purF145, respectively, with the F'32 episome.

Growth of bacterial strains. All strains were grown in the minimal medium E (14) with 0.5% glucose added as a carbon source, and appropriate supplements for auxotrophic strains. The cultures were incubated at 37°C in a New Brunswick rotary shaker. Bacterial growth was monitored turbidimetrically by measuring the absorbance of the culture at 650 nm. In our spectrophotometer, an absorbance of 0.500 corresponds to a bacterial density of 4 × 10^9 cells/ml and to 235 μg of cells (dry weight) per ml.

Assays. The uptake of [14C]-histidine was determined by the growing-cells method of Ames (1). Resistance to analogues was tested on a petri plate by streaking clones radially (from the center to the periphery) and placing in the center a filter paper disc impregnated with the analogue (on unsupplemented plates: 0.02 μmol of azaserine, 0.5 μmol of HIPA, or 0.1 μmol of 5-methyltryptophan; discs on plates supplemented with 3 × 10^{-2} M L-histidinol were impregnated with 5 μmol of HIPA). Colonies which grew near the center were scored as resistant.

Selection of revertants of histidine permease mutants. About 0.1 ml of a culture of the double-mutant (bearing deletion hisHB22 and hisP mutation) was spread on a minimal glucose plate containing 10^{-2} M phenylalanine and 10^{-4} M histidine. A very small crystal of N-methyl-N'-nitro-N-nitrosoguanidine was placed in the center, and the plates were incubated for about 4 days.

Test for the presence of amber suppressors. A method for determining the presence of amber suppressors has been described by Berkowitz et al. (5). In our experiments, colonies on the reversion plates prepared as described above were replicated on minimal plates, containing 3 × 10^{-2} M L-histidinol and 1% lactose as the carbon source with 0.1 ml of the tester strains (SB391 or SB392) spread on them. As a control, colonies on the reversion plates were first printed on the same medium without tester strain. The replicate plates were incubated for about 4 days. Strain SB391 has the following genotype, his644/F' lacX82. Strain SB392 has the following genotype, his644/F' lacU281. Both F' lac mutations are UAG mutations.

Genetic tests. Conjugation experiments were performed by the method of Sanderson and Demerec (11). All crosses were uninterrupted matings of 3-hr duration.

Transfer of episomes was performed by spreading together on a selective plate 0.1 ml each of the episome-containing and the recipient plates.

Transduction tests were performed by spreading together on a selective plate 0.1 ml of an overnight culture of the recipient strain and approximately 10^9 phage (P22 or P22-L4) which had been prepared on the donor strain. P22-L4 is a nonlysogenizing mutant of P22; it was isolated and donated by H. O. Smith. Materials. 4-C-L-histidine (about 300 μg/μmol) was purchased from New England Nuclear Corp., Boston, Mass. HIPA (13) and α-hydrazino-4-(p-hydroxyphenyl) propionic acid were gifts of F. A. Kuehl, Jr., of Merck Sharp and Dohme Research Laboratories, Rahway, N.J. Azaserine (O-diazoacetyl-L-serine) was obtained from E. P. Anderson. L-Histidinol and 5-methyl-β-tryptophan were purchased from Cyclo Chemical Corp., Los Angeles, Calif., and Mann Research Laboratories, New York, N.Y. respectively. N-methyl-N'-nitro-N-nitrosoguanidine was purchased from Aldrich Chemical Co., Inc., Milwaukee, Wisc. The 1-amino-2-(4-hydroxyphenyl) ethyl phosphonic acid and 1-amino-2-phenylethyl phosphonic acid were purchased from Calbiochem, Los Angeles, Calif.

RESULTS

Location of the hisP gene. The mutation responsible for HIPA resistance was located between the histidine operon and the purC locus. This was determined by the following conjugation experiment. Strain SR305 (HfrA, gal-1, his-, str-s) was mated with TA236 (hisP-, ile+, pro-, ade+, str-r). Selection was made singly for each auxotrophic marker, and the recombinants were tested for possession of the other, unselected markers. A more accurate location was obtained by two-point and three-point transduction tests with markers in the region of interest. Two-point transduction tests (Table 1) indicated that hisP mutations are very closely linked to purF. A 49% linkage was found between hisP1650 and purF145 and about 0.3% linkage between hisP1650 and arD5. Since purF and arD are known to be about 10% cotransducible, the order arD purF hisP was demonstrated. Three-point transduction tests confirmed this order (Table 2). Cross I indicates the order, arD purF hisP; cross II indicates the order, hisP

*Strain hisP1650 was used as the donor. The wild-type transductants were scored for HIPA resistance by the radial streak method. Numbers in parentheses indicate the number of colonies scored.
purF hisP. Since hisT is already known to be between aroD and purF (10), we inferred the gene order aroD hisT purF hisP (Fig. 1).

Properties of strains which are diploid for the hisP gene. The hisP+ allele carried by the E. coli F'32 episome was found dominant to a chromosomal hisP mutation (Table 3). This was determined by transferring the F'32 episome from strain TR11 (aroD5 cysC1112/F'32 dsd) to the double-mutant aroD5 hisP1654. Selection was made for growth on minimal medium. The resulting colonies were merozygotes, carrying mutant alleles of aroD and hisP in the chromosome and wild-type alleles in the episome. These colonies were then tested for sensitivity to inhibition by HIPA, and all were sensitive (Table 3). This phenomenon demonstrates the dominance of the episomal hisP+ gene over the mutant chromosomal hisP gene. The segregants which had lost F'32 (Table 3) had regained their requirement for aromatic amino acids simultaneously to resistance to HIPA. Thus, the phenotype of the merozygote is due to a dominance effect and not to recombination or reversion of any markers.

The effect of an added permease gene was to increase the sensitivity to HIPA inhibition (Fig. 2). Strain TR135, which was constructed by introducing the F'32 episome (hisP+) into a hisP+ strain, carries two wild-type hisP+ genes and is supersensitive to inhibition by HIPA when compared with the wild-type. In addition to the much larger zone of inhibition for the diploid strain (TR135), it is clear that no resistant mutants appear, whereas strains with only one hisP+ gene, such as wild-type or TR134 (hisP+/F'hisP+), yield many resistant colonies. This is to be expected, because a single hisP+ gene is sufficient to confer HIPA sensitivity (hisP+ being dominant over hisP), and simultaneous mutations to resistance in both genes (in TR135) would be extremely rare.

TR134 has a slightly larger zone of inhibition than wild-type, which suggests an intermediate level of permease activity. The presence of several episomal copies per cell [previously observed in other cases (6)] could be responsible for such

* For cross I, the donor was aroD5 hisP1654 and the recipient was purF145. For cross II, the donor was hisT1207 and the recipient was purF145 hisP1653. For both crosses I and II, selection was for Pur+. 

* This class is low because the two donor markers, aroD and hisP, are only weakly cotransducible (see Table 1) and thus are seldom carried by the same transducing fragment.

b Derived from merozygotes by loss of F'32.

FIG. 2. Response to inhibition by HIPA. TR134 is purF145 hisP1653/F'32hisP+. TR135 is purF145 hisP+/F'32 hisP+. Plates contain minimal medium and 0.5 μmole of HIPA on the disc. No resistant colonies appeared in the inhibited zone of TR135, even after several days of incubation.

increased permease activity. In fact, direct assay of permease activity in strains TR134, TR135, and the wild-type showed that HIPA sensitivity increased with increasing permease activity; TR135 (hisP+/F'hisP+) and TR134 (hisP/F'hisP+) had about 2 and 1.5 times the wild-type permease level, respectively (Fig. 3). Strain TR11, which is a merodiploid with two copies of the hisP+ gene (like TR135), had more than twice the wild-type level of histidine permease activity.

The absence of HIPA-resistant mutants in merodiploids having two wild-type copies of the hisP+ region (TR135, TR11) also demonstrates that the frequent, spontaneous, HIPA-resistant mutants occurring in the wild-type are all located in the chromosomal region homologous to F'32 genes and probably are all in the hisP gene (or genes).

Selection of revertants of hisP mutants. Histidine is transported by two different permeases,
the histidine-specific permease and the aromatic permease (1). Therefore, a histidine-requiring strain which lacks the histidine-specific permease (hisHB22 hisP1657) must depend on the second (aromatic) permease or on diffusion as a means of obtaining exogenous histidine. Transport of histidine through the aromatic permease can be inhibited by phenylalanine, tyrosine, and tryptophan. Figure 4 shows the growth response of mutants hisHB22 and hisHB22 hisP1657 to histidine in the presence and absence of tryptophan. At high exogenous concentration of histidine ($10^{-3} \text{M}$), mutant hisHB22 hisP1657 grew as well as hisHB22 (which has an intact histidine-specific permease) even with the addition of tryptophan; at such high concentration, histidine can presumably enter the cell by diffusion. At low histidine concentration ($7.7 \times 10^{-6} \text{M}$), hisHB22 grew normally until the histidine was completely exhausted, at which point growth terminated abruptly; since the histidine-specific permease was utilized, tryptophan had no effect on its growth. On the other hand, the histidine uptake in hisHB22 hisP1657 depended exclusively on the aromatic permease which had a much lower affinity for histidine ($K_m(\text{His}) = 10^{-4} \text{M}$); therefore, as the histidine supply was gradually depleted, growth of this strain was increasingly limited. Moreover, in the presence of tryptophan, the double-mutant (hisHB22 hisP1657) was unable to grow, since histidine uptake was completely prevented; mutation (hisP1657) had eliminated the histidine-specific permease, whereas excess tryptophan prevented the general aromatic permease from transporting histidine. Inhibition of strain hisHB22 hisP1657 by tryptophan can also be demonstrated on a petri plate. A lawn of hisHB22 hisP1657 on a plate containing $3 \times 10^{-4} \text{M}$ histidine was inhibited by tryptophan diffusing from a filter paper disc (Fig. 5). Revertants of hisP mutants, and hisP+ recombinants between hisP mutants, can be selected as colonies that are resistant to tryptophan inhibition. This selection permits both a recombinational analysis of the hisP gene and the classification of permease mutants by studying their reversion (5, 15).

**Presence of amber mutations in hisP gene(s).** The isolation of amber hisP mutants demonstrated that this gene(s) codes for a protein. All the available independent hisP mutants containing hisHB22 were reverted with methyl-nitro-
which is cotransducible with aroP; less than 2% cotransducibility was observed between azaserine resistance and the following markers: argF, leu500, purH, argA, purA, pyrB, ara, proA, pan.

Properties of the aromatic permease. The specificity of the aromatic permease was investigated to gain information about the interaction between substrate and permease. A survey of the characteristics of the known substrates of the aromatic permease indicated that the nature of the side chain can vary considerably, although some aromatic character seems necessary. In fact, the following compounds, which have quite a variety of substitutions in the side chain, have been shown to be substrates of the aromatic permease (1): the natural amino acids, tyrosine, phenylalanine, tryptophan, and histidine; the amino acid analogues, 3-pyrrozolealanine, 2-thiazolealanine, β-2-thiencylaniline, β-3-furylalanine, o-, m-, and p-fluorophenylalanine, o-aminophenylalanine, 5-methyl-tryptophan, 2-methyl-histidine, among many others. Azaserine is unusual because, although it does not have a ring structure, it is a substrate.

This permease had no stringent requirement for the presence of the carboxyl group. In fact, analogues of the aromatic amino acids containing a phosphonic acid group instead of a carboxyl group were transported as demonstrated by the following facts. (i) Both the tyrosine and the phenylalanine phosphonate derivatives were very good inhibitors of growth of the wild-type, and tryptophan completely reversed this inhibition.

(ii) Mutants resistant to inhibition by either of these analogues had simultaneously acquired resistance to azaserine, which is an indication of a defective aromatic permease. (iii) Aromatic permease mutant, aroP504, was resistant to the phenylalanine phosphonate analogue. (iv) Dopamine, which can be considered an analogue lacking completely the carboxyl group, reversed the inhibition caused by azaserine. There is no evidence that dopamine actually entered the cells, but its reversal of azaserine inhibition indicated that it can interfere with the action of the aromatic permease, and it gives indirect evidence that this permease does not require a carboxyl group for recognition of substrate.

Direct evidence that the aromatic permease transports amines or amino-alcohols was sought by testing the following compounds for inhibitory action: tyramine, tryptamine, phenylethylamine, tyrosinol, tryptophol, and phenylalaninol. Either they did not inhibit growth, or, if they did, the inhibition was achieved at very high concen-
trations (10^{-8} M or higher), and strain *aroP504* was as sensitive as the wild-type. At such high concentrations, several permeases or diffusion might also be involved in transport, besides, possibly, the aromatic permease. This could explain the sensitivity of *aroP504* to these compounds. Therefore, it was impossible to confirm unequivocally or exclude that compounds lacking a carboxyl group are substrates of the aromatic permease.

The hydrazino analogues of both tyrosine and histidine (HIPA) are transported by the aromatic permease because tryptophan partially reversed their inhibition of growth and because of the partial resistance of *aroP504* to inhibition by hydrazino tyrosine. Therefore, the aromatic permease is able to handle compounds in which hydrazino groups substitute for amino groups.

**DISCUSSION**

This paper further characterizes the specific histidine permease and the aromatic permease.

The map position of *hisP* has been accurately established, and it is dissimilar to that of any of the presently known histidine regulatory and biosynthetic genes (3, 4). This suggests, although it does not exclude, that intermediates involved in the active transport of histidine do not have a regulatory function for the histidine biosynthetic system. It has been previously established (9) that it is not necessary for histidine to be transported by the specific permease to repress the histidine operon (as demonstrated in the constitutive *hisS* mutants, which have a defective histidine-activating enzyme).

The wild type allele *hisP* is dominant over *hisP*, as expected when the mutated gene no longer produces a functional protein.

The increased histidine permease activity in merozygotes which have two wild-type *hisP* loci indicates that the gene (or genes) which is limiting for the measurement of histidine transport is located in the section of chromosome covered by the F′ episome. This does not exclude the possibility that other genes involved in histidine transport are present in other parts of the chromosome. However, this seems unlikely because (i) all *hisP* mutants which have been isolated map in the *hisP* region; and (ii) a merozygote with two wild-type *hisP* loci does not yield any resistant mutants. Therefore, if there are other loci involved in histidine transport, mutation in these loci must be lethal or not responsive to our selection methods.

The use of double-mutants, histidine-requiring and *hisP*, has supplied the means of selecting for revertants and recombinants of *hisP* mutants because of the inhibition by aromatic amino acids when growing on limiting histidine. This has allowed us to detect the presence of amber mutants in the *hisP* locus by checking *hisP* revertants for the existence of amber suppressors. This method will also be used for studying recombination and complementation among different *hisP* mutants. The occurrence of *hisP* amber mutants indicates that the product of this locus is a protein.

The amber mutant, *hisP1661*, when introduced into an otherwise wild-type genome, does not cause any decrease in growth rate. Therefore, it is concluded that the product of the *hisP* gene is completely dispensable under these conditions.

The location of the *hisP* and *aroP* genes in the bacterial map indicates that no linkage exists between these two permease genes. A gene apparently involved in transport of glutamate has been mapped in *E. coli* (7) and has a position quite distant from that of either *hisP* or *aroP* (assuming that the positions of these genes are analogous in *E. coli* and *S. typhimurium*, as are the positions of most other genes). The gene for arginine permease has been located near *serA* in *E. coli* (W. Maas, personal communication). No other amino acid permease has been mapped in either *E. coli* or *S. typhimurium*, but from this limited knowledge, it seems that no specific site exists for the common location of all permease genes. In addition, the *hisP* gene is unlinked to the histidine operon.

The aromatic permease has a broad specificity. The fact that it can transport phosphonic acid analogues of the amino acids makes unlikely the possibility that the biochemical mechanism involves a carboxyl activation.

Both the histidine-specific permease (12) and the aromatic permease can transport α-hydrazino analogues of the amino acids. Apparently, no irreversible reaction occurs between these compounds and the components of the transport mechanism because the analogues are released on the inside of the cell where the inhibitory activity occurs. This phenomenon suggests that pyridoxal phosphate is not involved in the transport system because HIPA reacts with it irreversibly (12).
